ESR spectra of  $\text{Fe}^{3+}$  Ions in lead silicate slags<sup>†</sup>

Nobuya IWAMOTO\*, Yukio MAKINO\*\* and Hirosuke MIKAMI\*\*\*

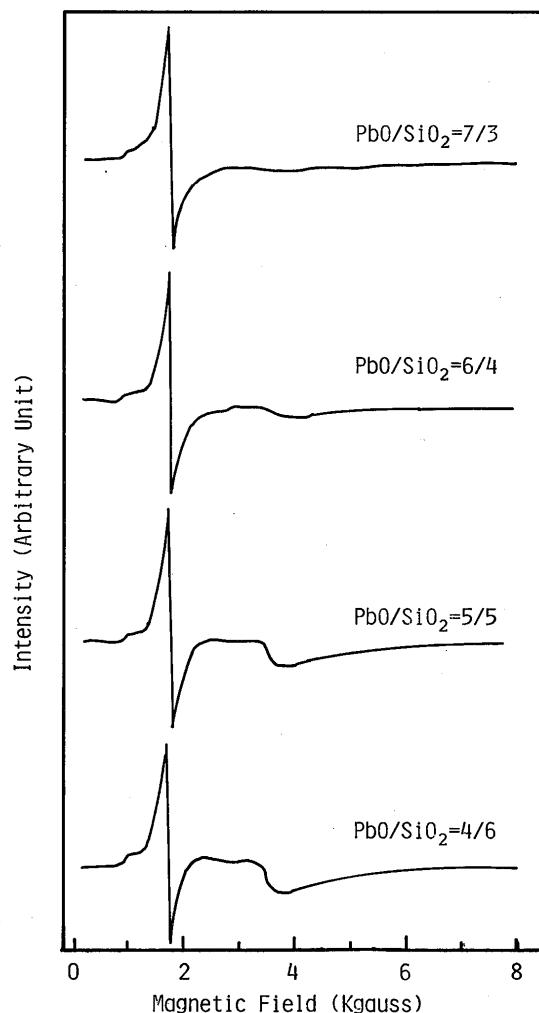

KEY WORDS (Electron Spin Resonance) (Lead Silicate) (State Analysis) ( $\text{Fe}^{3+}$  Ion)

Lead silicate glass has been widely investigated by various spectroscopic methods<sup>1)-3)</sup> in order to elucidate the structure of silicate glass and its melt. On the other hand, the clarification of state of iron in slags is very important in iron- and steel-making and in some welding processes using fluxes<sup>4)-6)</sup>. In this study, state of ferric ions in lead silicate glasses was investigated by electron spin resonance (ESR) spectroscopy.

Reagent grade  $\text{SiO}_2$ ,  $\text{PbO}$  and  $\text{Fe}_2\text{O}_3$  were used for preparing glass specimens. The mixtures of these reagents were melted in platinum crucibles at the temperatures 100°C higher than their liquidus temperatures in an electric furnace.  $\text{Fe}_2\text{O}_3$  addition was fixed to be 0.5mol% in every glass. After being held for 1 hr in air, they were cooled. ESR spectra were measured with X-band method using a spectrometer of Varian E-109 type. Relative quantity of  $\text{Fe}^{3+}$  ions related to each resonance was approximately estimated by  $I(\Delta H)^2$ , where  $I$  and  $\Delta H$  are the peak-to-peak height and width of the resonance.

ESR spectra of  $\text{Fe}^{3+}$  ions in lead silicate glasses are shown in Fig. 1. Two resonances are observed near  $g=2.0$  ( $H=3400$  G) and  $g=4.3$  ( $H=1600$  G), respectively. A shoulder is observed near  $g=6.0$  ( $H=1050$  G). According to the previous papers<sup>7)-10)</sup>, the  $g=4.3$  and  $g=6.0$  resonances arise from  $\text{Fe}^{3+}$  ions in a rhombic and axial crystal fields, respectively. The  $g=2.0$  resonance can arise from two sorts of origins, that is, from dipole-dipole interacted  $\text{Fe}^{3+}$  ions and  $\text{Fe}^{3+}$  ions in an axial crystal field. Further, it is indicated that the  $g=2.0$  resonance due to dipole-dipole interaction between  $\text{Fe}^{3+}$  ions begins to be observed at the content of  $\text{Fe}_2\text{O}_3$  more than 1 mol%. As shown in Fig. 1, the intensity of the shoulder near  $g=6.0$  has a tendency to increase with increasing the intensity of the  $g=2.0$  resonance. Accordingly, it is reasonable to assign the  $g=2.0$  resonance not to dipole-dipole interacted  $\text{Fe}^{3+}$  ions but to  $\text{Fe}^{3+}$  ions in an axial crystal field. Figure 2 shows the composition depend-

ence of the relative quantities of  $\text{Fe}^{3+}$  ions related to the  $g=2.0$  and  $g=4.3$  resonances. The relative quantity of  $\text{Fe}^{3+}$  ions related to the  $g=4.3$  resonance,  $r_{g=4.3}$ , is nearly constant at the content less than about 50mol% and it increases with increasing  $\text{PbO}$  content when  $\text{PbO}$  content is over 50 mol%. This shows that  $\text{Fe}^{3+}$  ions have a tendency to prefer rhombic crystal field to axial one with increasing  $\text{PbO}$  content. The observa-

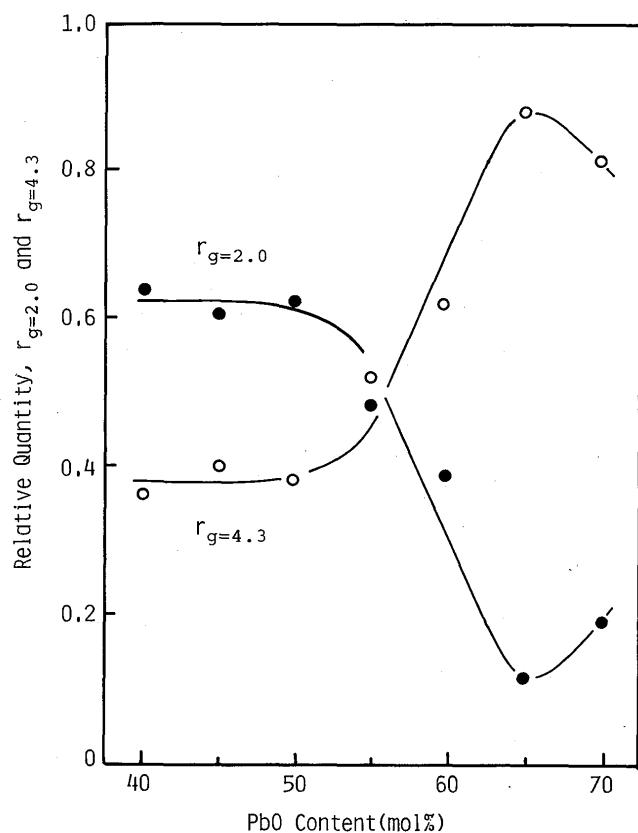

Fig. 2 Dependences of relative quantities,  $r_g=2.0$  and  $r_g=4.3$  upon PbO content.

tion of the tendency at the PbO content more than 50 mol% suggests that the increase of  $\text{Fe}^{3+}$  ions in a rhombic crystal field is closely related to the change of network structure to linear chain structure in lead silicate glass. The relation between state of  $\text{Fe}^{3+}$  ion and silicate structure will be investigated in near future.
