(Received 6 May 2010; accepted 9 August 2010; published online 14 October 2010)

A neutron source for neutron resonance spectroscopy has been developed using high-intensity, short-pulse lasers. This technique will allow robust measurement of interior ion temperature of laser-shocked materials and provide insight into material equation of state. The neutron generation technique uses laser-accelerated protons to create neutrons in LiF through \((p,n)\) reactions. The incident proton beam has been diagnosed using radiochromic film. This distribution is used as the input for a \((p,n)\) neutron prediction code which is validated with experimentally measured neutron yields. The calculation infers a total fluence of \(1.8 \times 10^9\) neutrons, which are expected to be sufficient for neutron resonance spectroscopy temperature measurements. © 2010 American Institute of Physics. [doi:10.1063/1.3484218]

A concrete understanding of material equation of state (EOS) is of underlying importance in many fields (e.g., planetary physics, geophysics, shocked matter physics, and warm-dense matter physics). One of the most fundamental quantities in EOS measurement is temperature, which is rarely measured. A major hurdle to temperature measurements is that conventional optical diagnostic techniques cannot be used to probe the interior of opaque materials, such as metals, while surface or interface techniques are inherently complex. A technique known as neutron resonance spectroscopy (NRS) avoids this problem by using neutrons to diagnose temperature.

In NRS, a beam of neutrons, with energies of \(1–100\,\text{eV}\), is sent through a sample made of or doped with a material possessing strong neutron absorption resonances at these energies (e.g., W and Mo). When passing through, the material neutrons are absorbed by nuclear resonances in the ions, which can be seen as negative-peaks in the resulting neutron spectrum. From these peaks, the spectral broadening and shifting can be measured, enabling determination of ion temperature and velocity, respectively.

So far, NRS experiments have been performed using spallation neutrons from a proton accelerator ring. These experiments probed a shocked Mo target doped with W and inferred a corrected temperature\(^2\) of around 700 K with error bars of \(\pm 100\,\text{K}\); these error bars are lower than currently demonstrated with other nonoptical measurement techniques (e.g., x-ray Thomson scattering). However, in order to provide shocked states for EOS investigation at these facilities, detonation of chemical explosives accelerates flyer plates into the material of interest. This technique is difficult and expensive to employ. On the other hand, nanosecond lasers have been used extensively to study shocked\(^3\) and warm-dense matter.\(^4\) Many of these laser facilities are equipped with high intensity, short pulse lasers that can be used concurrently with the nanosecond laser pulse.

The use of high power, high intensity laser beams to accelerate protons has been well studied.\(^5–9\) In 2004 Lancaster et al.,\(^10\) according to our knowledge, were the first to show the conversion of these laser-generated protons into neutrons by directing these protons on a LiF slab and taking advantage of the \(^7\text{Li}(p,n)^7\text{Be}\) reaction. More recently, Davis et al.\(^11\) showed numerical modeling of the \(^7\text{Li}(d,xn)\) reaction using laser-accelerated deuterons. This work shows significant potential for creating a large amount neutrons with high energy (>15 MeV) using a petawatt class laser.

In the NRS scheme, the laser-generated neutrons are moderated down to appropriate epithermal energies. The picosecond scale pulse length of the laser (as with the accelerator beam) and the ability to dope only a given section of the material, enables temporal and spatial effects (e.g., rarefaction) to be minimized. In this letter, it is shown that neutrons produced through \((p,n)\) reactions with laser accelerated protons are a route to performing NRS measurements in laser shocked materials.

The experiment was performed on the Titan Laser of the Jupiter Laser Facility at the Lawrence Livermore National Laboratory. The Titan laser is a Nd:glass laser with \(\lambda_{\text{laser}} = 1054\,\text{nm}\), used at best focus (spot diameter of \(7\,\mu\text{m}\) with 20% of energy) and shortest pulse length, 0.7 ps. The laser was focused on Cu foil of \(25\,\mu\text{m}\) thickness, which accelerated high energy electrons in the forward direction setting up an electric field that accelerated a quasineutral proton beam from a hydrocarbon debris layer on the rear of the target. In phase I, these protons were incident on a radiochromic film (RCF) stack (see phase I of Fig. 1) to measure the proton distribution or, in phase II, they were incident on a 0.9 mm LiF converter foil (see phase II of Fig. 1). The LiF converter foil contains large cross-sections for \((p,n)\) reactions (see...
Fig. 1. (Color online) Experimental layout showing phase I, measurement of proton distribution using RCF and phase II showing neutron production through \(^{12} \text{Li}(p,n)^{7} \text{Be}\) reactions and neutron measurement using CR-39.

Fig. 4 below) which generated neutrons that were detected on absolutely calibrated CR-39 detectors at three different angles.

In phase I, RCF stacks were used to characterize the proton beam distribution. RCF is an absolutely calibrated film\(^\text{12}\) which contains an organic dye that increases in opacity with exposure to ionizing radiation. The RCF stack consists of alternating layers of Al filters and RCF. A total of ten sheets of RCF were used to give an energy resolution from 5.1 to 42.5 MeV. The lower limit was chosen to avoid signal contamination from other high energy ions accelerated off the foil. Note that the lower limit does not add significant error to our neutron predictions as the probability of neutron production at lower energies is quite small (see Fig. 5 below). The stopping of the protons and the energy that they deposited in each layer of film was calculated with the collisional Monte-Carlo code SRIM.\(^\text{13}\)

In order to fit the data, a two temperature Maxwellian distribution was assumed, 
\[
dN/d\varepsilon = (N_1/\sqrt{\pi\varepsilon T_1})e^{-\varepsilon/T_1} + (N_2/\sqrt{\pi\varepsilon T_2})e^{-\varepsilon/T_2},
\]
which is a function of proton energy \(\varepsilon\). The parameters \(N_1\), \(N_2\), \(T_1\), and \(T_2\) representing proton number and proton temperature, respectively, were optimized to minimize the reduced \(\chi^2\) fit to the data. This fit is compared with experimental data, shown in Fig. 2. The best fit is given by \(T_1=2.9\) MeV, \(N_1=4.34 \times 10^{13}\), \(T_2=10.27\) MeV, and \(N_2=5.44 \times 10^{12}\), with a reduced \(\chi^2\) of 0.41. The conversion efficiency into protons above 5.1 MeV is 3.5% with is consistent with previous results.\(^\text{9}\)

The largest error in the RCF comes from the batch to batch error which is 10%.\(^\text{12}\) The spectral distribution from above is shown in Fig. 3. Also shown is the proton spectrum inferred from a shot with similar laser parameters to illustrate shot-to-shot variation.

In phase II, a LiF block of 0.9 mm was placed about 1 mm behind the rear of the Cu foil so that the proton beam was incident on the LiF converter. RCF was not used concurrently, as the proton beam was obstructed by the LiF converter. In order to record the neutron emission, three stacks of absolutely calibrated CR-39 detectors were placed at 22°, 90°, and 158° from rear target normal at distances from 5 to 8.5 cm from the target. CR-39 is a plastic that can be damaged indirectly by neutrons through knock-on protons and has been used previously in laser generated proton experiments.\(^\text{10}\) Due to the sensitivity of CR-39 to protons, the CR-39 was shielded with 3.175 mm thick Al on the 90° and 158° pieces and 6.35 mm thick Al on the 22° piece. The effectiveness of these filters was demonstrated by using RCF...
FIG. 4. (Color online) Plotted on the left axis, are cross-sections for
\(^7\text{Li}(p,n)^7\text{Be}\) (solid line) and \(^{19}\text{F}(p,n)^{19}\text{Ne}\) (dashed line) vs incident proton
energy. The other stable isotope of Li is \(^6\text{Li}\) which has no documented \((p,n)\)
cross-sections and makes up only 7.5% of naturally occurring Li. On the
right axis is the mean stopping range of protons in LiF as calculated with
SRIM (dash-dotted line).

Instead of CR-39 and verifying that there was no noticeable
signal.

To determine the sensitivity of CR-39 to neutrons, a
\(^{252}\text{Cf}\) source was used. This is a reasonable assumption given
that the CR-39 sensitivity is nearly constant with neutrons,
0.5–5 MeV.\(^{14}\) The error in this measurement is calculated by
adding in quadrature the variation in the background of un-
exposed CR-39 and the variation in the signal of the three
CR-39 pieces within the detector stack.

The code DOWNSPEC (Ref. 15) was used to calculate the
production of neutrons created in a given \((p,n)\) converter
material by given energy protons. The code simultaneously
calculated the stopping of incident protons as well as calcu-
lating their cross-sections for \((p,n)\) type reactions (see Fig.
4). This allows for determination of angular and energy re-
solved neutron yields. The code uses the continuous decel-
eration approximation model so it does not account for scat-
ttering or for energy broadening for a single energy incident
proton.

A useful way to evaluate a material’s ability to produce
\((p,n)\) neutrons is to look at neutrons produced per incident
proton at a given energy, as shown in Fig. 5. This is more
useful than the cross-section alone because it also takes into
account the stopping of protons in the material.

To predict the number of neutrons produced, the proton
distributions (see Fig. 2) were used as inputs in DOWNSPEC,
which gave angularly resolved neutron yields. These pre-
dicted yields are plotted in Fig. 6 against experimentally
measured CR-39 yields. It is worth noting that there is shot-
to-shot variation even with the same laser energy. This fluc-
tuation is common in short pulse laser experiments.\(^8,9\)

In this letter, the capacity to predict and generate beams of
1.8 \times 10^7 neutrons within a few picoseconds has been
demonstrated. Using statistical error analysis, the predicted
fractional uncertainty in NRS temperature measurements is
\(\Delta T/T=2/\sqrt{N}\) where \(N\) is the number of neutrons that are
usable for NRS measurements (i.e., they pass through the
target and are in the region of resonance), \(\sqrt{N}\) is the statistical
noise and 2 is the number of degrees of freedom (i.e., location
and width of resonance). Thus for temperature measure-
ment with 1% accuracy, 4 \times 10^4 usable neutrons are required.
The moderator setup must therefore capture the high energy
neutrons, direct them toward the shocked target, and down-
shift their energy with an efficiency of \(>2.2 \times 10^{-5}\).

The feasibility of NRS is highly dependent on the shock
experiment to be measured. The choice of material being
shocked or used as a dopant is significant due to the variation
of incident neutron energies at which neutron resonances oc-
cur and the strength of these cross-sections. Other factors

FIG. 5. Angularly integrated neutron production probability of protons of a
given energy in LiF. The solid line is for 0.9 mm thickness, as used in the
experiment, and the dotted line is for an infinite block of LiF.

FIG. 6. (Color online) Experimental neutron yields (CR-39) plotted against
predicted yields. Two shots of 127 J plotted with diamonds (●) and one
shot of 114 J is shown with squares (■). The predicted yield, using a 140 J
shot, is shown as the solid line. The error bars are due to variation of the
background and signal of the CR-39 stacks.
such as the dopant level and the solid angle subtended by the neutron detector during the shock experiment are also critically important. Preliminary analysis using a polyethylene moderator, in a geometry relevant to a laser facility, suggests that NRS can be successfully fielded as a temperature measurement technique in the laser environment.

To conclude, the viability of short-pulse laser produced epithermal neutrons as viable path for a NRS temperature diagnostic has been shown. Future experiments on the Titan laser will illustrate the capacity to moderate and collimate neutrons for NRS and to ultimately perform NRS temperature measurements on a sample ablatively loaded with a nanosecond laser pulse.
