(Received 16 November 1999; accepted 4 February 2000)

Laser plasma interactions in a relativistic parameter regime have been intensively investigated for studying the possibility of fast ignition in inertial confinement fusion (ICF). Using ultra-intense laser systems and particle-in-cell (PIC) simulation codes, relativistic laser light self-focusing, super hot electrons, ions, and neutron production, are studied. The experiments are performed with ultra-intense laser with 50 J energy, 0.5–1 ps pulse at 1053 nm laser wavelength at a laser intensity of 10^{19} W/cm². Most of the laser shots are studied under preformed plasma conditions with a 100 μ m plasma scale length condition. In the study of laser pulse behavior in the preformed plasmas, a special mode has been observed which penetrated the preformed plasma all the way very close to the original planar target surface. On these shots, super hot electrons have been observed with its energy peak exceeding 1 MeV. The energy transport of the hot electrons has been studied with making use of $K\alpha$ emissions from a seeded metal layer in planar targets. The details of ion acceleration followed by beam fusion reaction have been studied with neutron spectrometers. Laser ponderomotive force self-focusing and hot electron generation have been applied to a compressed core to see the effect of heating by injecting 12 beams of 100 ps, 1 TW pulses. © 2000 American Institute of Physics. [S1070-664X(00)95605-2]

I. INTRODUCTION

The concept of fast ignition (FI) (Refs. 1 and 2) is to inject an ultra-intense short laser pulse(s) into a highly compressed, high density fuel core within the core disassembling time, making use of relativistic laser self-focusing or guided channel formation. The ignition may be performed with the use of hot electrons or energetic ions, whose temperatures are of the order of MeV, much higher than the thermal temperature of the plasmas. The attractive points of the concept are possibly to obtain fusion gains much higher and requiring laser irradiation uniformity less than those in the central spark scheme in inertial confinement fusion (ICF). The chirped pulse amplification method³ made it possible to construct ultra-intense laser systems with 100 TW to PW peak intensities. Laser plasma interactions using these laser systems have opened new research in relativistic laser plasma

interactions.^{4–6} The new experimental possibilities can be applied also to many other fields, such as particle acceleration, medical and industrial radiography, x-ray laser, and laboratory astrophysics.

We have studied the ultra-intense laser plasma interactions related to fast ignitor in ICF using our 50–100 TW laser systems and particle-in-cell (PIC) simulation codes. Among the issues to be studied, we focused on the laser beam behavior in plasmas, super hot electron generation, energetic ion production, and subsequent beam fusion process. As the second set of experiments, laser ponderomotive force self-focusing^{7,9} and hot electron generation have been applied to a compressed core to see the effect of heating by injecting 12 beams of 100 ps, 1 TW pulses in order to model the fast ignition scheme.

II. EXPERIMENTAL FACILITIES

Experiments were conducted using the 100 TW laser [peta watt module (PWM)] line coupled with the GEKKO XII laser system. With the conventional chirped pulse amplification (CPA) technique, the pulse in the PWM can deliver a 50 J with a 0.5–1 ps pulse at a 1 μ m laser wavelength. Twenty percent of the ultra-short pulse energy can be focused to a spot size of 10 μ m full-width at half-maximum (FWHM) using an F/3.5 on-axis parabola at a vacuum inten-

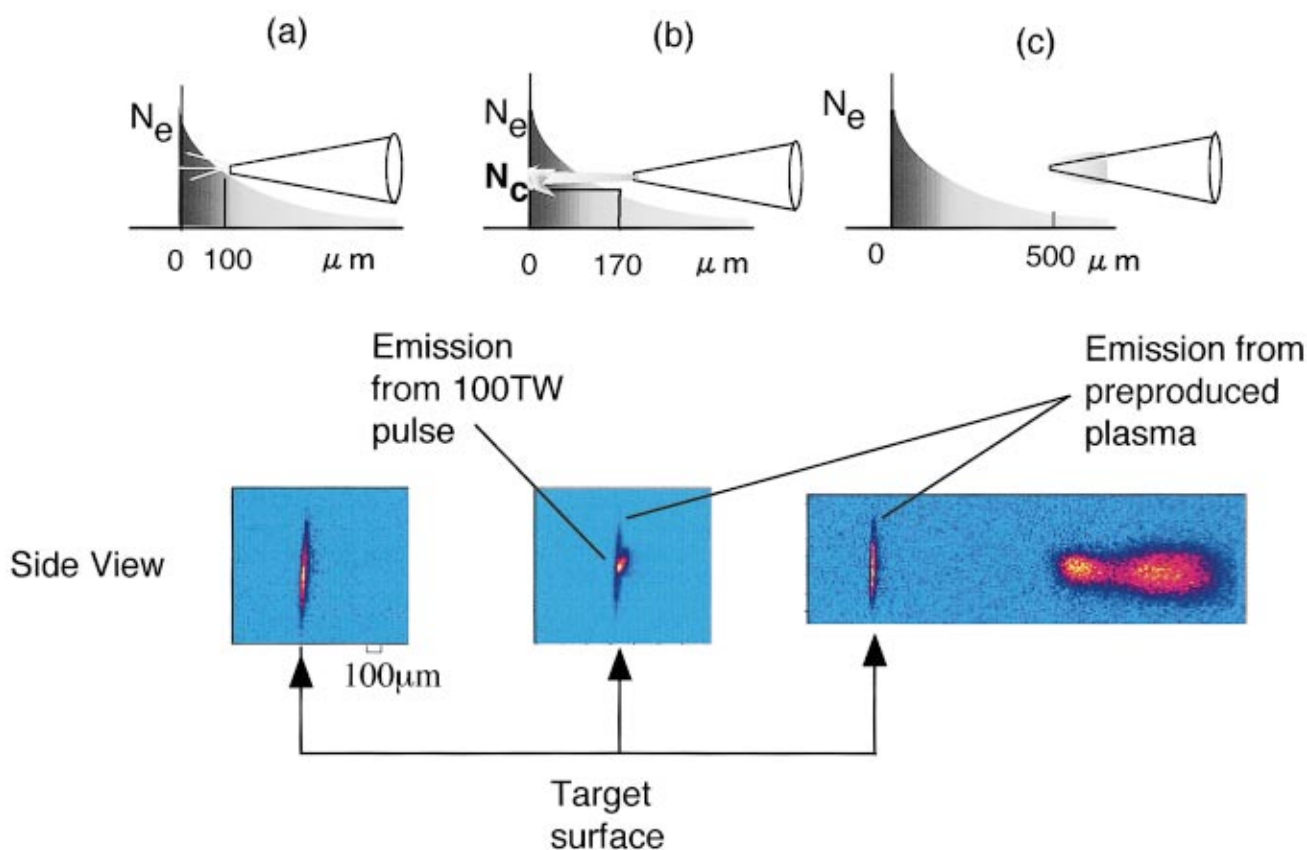

FIG. 1. (Color) X-ray pinhole pictures of ultra-intense laser shot into a plasma (side-on view). The focus point was set at (a) 100 μm , (b) 170 μm , and (c) 500 μm from the original planar target surface. A clear local emission on the target surface seen in (b) is due to the penetration of the ultra-intense laser pulse.

sity of 10^{18} – 10^{19} W/cm². Preformed plasmas were created by focusing a 100 ps laser pulse of any beam of the GEKKO XII at the wavelengths either 1 μm or 0.53 μm , or focusing a 1 ns partially coherent laser pulse at 1 μm or 0.5 μm within a 500 μm spot size. All 12 arms of the GEKKO XII can deliver partially coherent laser (PCL) pulses of 1 ns (square shape) with 100 J/pulse at 1 μm followed by 100 ps double pulses with 120 J/pulse energy at 1 μm . The PCL laser has a large divergence angle of 120 μrad , resulting in a 150 μm diam in the far field spot. The 100 ps double pulses have been used for hole boring^{7–9} a corona plasma by focusing tightly in front of the shell target surface.

III. EXPERIMENTS AND RESULTS

Our experiments related to fast ignitor have been conducted as follows. First, three categories are performed with an ultra-short pulse at 10^{19} W/cm² laser intensity. The last category is with a short pulse at 10^{17} W/cm².

Those are

- (1) Ultra-intense laser behaviors in preformed plasmas;
- (2) Hot electron generation and its heating of a solid target;
- (3) Energetic ion generation and its subsequent fusion process; and
- (4) First demonstration of a compressed core heated by short pulse self-focusing and hot electrons.

A. Ultra-intense laser behaviors in preformed plasmas

It is an important subject for the fast ignitor concept to know if an ultra-intense laser with an intensity exceeding 10^{19} W/cm² can penetrate a thick corona plasma with whole beam relativistic self-focusing. There are several works about relativistic self-focusing in plasmas, both theoretical simulation and experiments.^{10,11} However, all the previous works dealt with the self-focusing with underdense plasmas or in a thin overdense plasma. It is more desirable for FI to study the details of relativistic self-focusing behaviors in a long exponential profile with a large overdense region. We have studied laser light behaviors in preproduced plasmas with a 100 μm density scale length created on a solid planar plastic target. The density profile of the preproduced plasma along the laser axis had the critical density (n_c) for 1 μm laser light at 100 μm from the target surface. The plasma is close to the ones used in our previous studies.

The experiments were carried out with the $\lambda=1.053$ μm , 100 TW laser line synchronized with the GEKKO XII laser system within a time jitter of less than 100 ps. Thus any of the GEKKO XII laser system's 12 beams could be used to create preproduced plasma at $\lambda=0.53$ μm , with a pulse width from 0.1 ns.

A relativistic self-focusing experiment has been conducted changing the focal position of the 100 TW beam along the laser axis relative to the preproduced plasma.¹² The preproduced plasmas were created on planar CD (deuterated

FIG. 2. (Color) 3D particle-in-cell (PIC) simulation result of a super penetration shot. (a) Condition for the simulation, (b) electron density distribution.

carbon) targets. The focal positions vary from 100 to 600 μm from the original target surface. The x-ray side-on pictures of those shots are shown in Fig. 1. Figures 1(a), 1(b), and 1(c) correspond to the focal positions of 100, 170, and 500 μm . In Figs. 1(a) and 1(c) there are large diameter emissions from the target surface, which come from the preproduced plasma created at a laser intensity (I_L) of 10^{15} W/cm^2 within a 500 μm diam spot. There is a distinctive difference in Fig. 1(b) compared to the other two pictures. In Fig. 1(b) one can see a local emission of less than 30 μm overlapped on the preproduced plasma almost on the target surface, as well as on the laser axis. In Fig. 1(c) a large x-ray emission is observed in the underdense plasma region. In our previous studies of ponderomotive type laser self-focusing, we have measured a whole beam self-focusing with various diagnostics. Those are x-ray pinhole cameras, Doppler spectrum measurement in the backscattered laser light from the penetrating self-focusing head in the plasma,⁷ and ultraviolet (UV) (Ref. 8) and x-ray laser⁹ probe beams. In these experiments, a 100 ps pulse at 10^{17} W/cm^2 at 1 μm was focused in a preproduced plasma at 250 μm from the original target surface. We could show a very good correlation between the side-on x-ray pinhole pictures and whole beam self-focusing, which was monitored directly by the UV and x-ray laser probes. Namely, when the laser light penetrate in a preproduced plasma as a whole beam self-focusing, and reached the sur-

face of a planar target, a strong local x-ray emission of a 30 μm diameter was observed from both side and front directions equivalent to the focal spot in vacuum. In our 100 TW laser experiment, the intense, locally emitted x-ray spot in Fig. 1(b) indicates that the ultra-intense laser light has penetrated in this thick preproduced plasma all the way, close to the target surface. There is another possibility to explain the local emission observed in Fig. 1(b), namely, by the hot electron themselves. However, the hot electron beam has a finite beam divergence angle, which is of the order of 30° .¹² Considering the finite divergence angle of the hot electron beam, the observed local spot of about 30 μm implies that the laser penetrated into the preproduced plasma and reached somewhere close to a point at 50 μm from the target surface. A three-dimensional (3D) PIC simulation was run to study the self-focusing in a plasma with an exponential density profile.¹³ In the simulation a 100 TW, 400 fs laser pulse was focused down to $5 \times 10^{19} \text{ W/cm}^2$ incident on a plasma with a density rising from 0 to $10 n_c$ over 30 μm and then remaining constant as shown in Fig. 2(a). The results are shown in Fig. 2(b) and 2(c). The laser self-focuses to an intensity of 10^{21} W/cm^2 in the channel and continues the propagation. In Fig. 2(b) the electron plasma density profile shows a clear channel formation, while the laser intensity distribution in Fig. 2(c) indicates a relativistic self-focusing. Such ultra-intense laser propagates into the overdense plasma even if

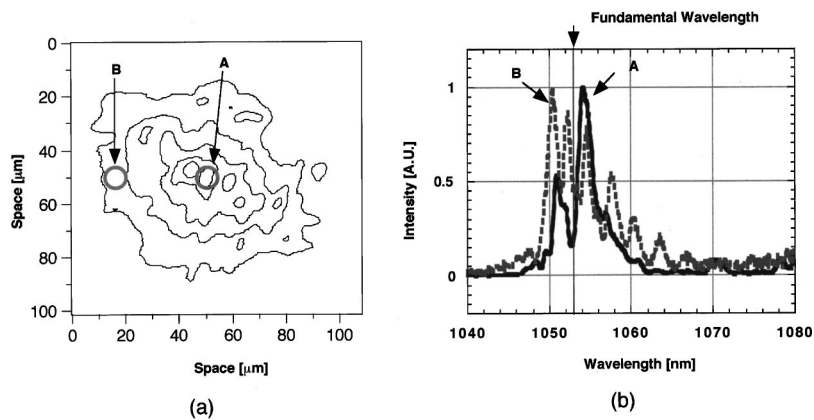

FIG. 3. (a) Focal spot image of the ultra-intense laser pulse backscattered from a preproduced plasma and (b) spectra of the focal image. The focal spot was imaged onto a fiber array and each fiber could give space resolved spectra. The spectral curves of A and B in (b) correspond to the spectra of spots A and B in (a).

the density is as high as 10 times n_c . A similar result has been obtained in our 2D PIC simulation.

Backscattered laser light from the preproduced plasma was measured with both spatial and spectral resolutions.¹⁴ A parabola focus mirror of F/3.5, which was used to irradiate the preproduced plasma, collected the backscattered light. The backscattered light was then image-relayed onto a bundle of 100 fibers (input) with a magnification of 15.4. The other side of the fiber bundle (output) was rearranged as a one-dimensional array of fibers. This array was attached on the entrance slit of a 1/4 m spectrometer. The exit slit image of the spectrometer shows the spectral dispersion in the horizontal direction and corresponds to each fiber in the vertical direction. Each vertical position corresponds to a part of focal area of 8 μm diam. Figure 3(a) shows the image of the focal plane area in the plasma. The image was taken on the super penetrating shot of Fig. 1. A few intense hot spots are observed within the focal spot area. The spectra of one hot spot [A in Fig. 3(a)] and another part [B in Fig. 3(a)] in the weaker intensity region are shown in Fig. 3(b). The observed spectra are totally different between the hot spot and the other part within the focal area. This data indicates that the both spatial and spectral resolutions are necessary for spectral measurement of scattered light. The regularly spaced spectral peaks in Fig. 3(b) are unique and interesting. If we assume that the peaks are due to stimulated Brillouin scattering and its subsequent decay into several daughter waves, the spectral spacing between the first and second corresponds to $2k_L C_s$, where k_L is the pump laser wave number and C_s ($= (T_e/M)^{1/2}$) is the ion acoustic speed. Here T_e is the plasma electron temperature and M is the ion mass. Since C_s is proportional to $(T_e)^{1/2}$, the background coronal temperature may be estimated to be about 6 keV.

B. Hot electron generation

On these super penetration shots, energetic electrons are measured both inside and outside the target. Electrons can be accelerated via $J \times B$ force (J , electron current in the laser electric field and B , laser magnetic field), vacuum heating, and stimulated Raman scattering, etc.¹⁵ Electron spectrometers use a pair of magnet plates with a 1.2 kGauss magnet strength. Since strong electromagnetic noise screens the most of the electrical diagnostics from 100 TW shots, an imaging

plate¹⁶ has been used as a detector. Figure 4 shows a typical hot electron spectrum measured at a 10^{19} W/cm^2 irradiation intensity for a case with the preproduced plasma. The horizontal axis shows the electron energy and the vertical shows the spectral intensity. The spectrum was measured at 19° from the laser forward axis in the horizontal plane and -45° in the longitude. The peak of the spectrum is at around 1 MeV. The spectrum shows hot electrons energetic enough for fast ignitor heating.¹ The suggested temperature is about 2 MeV.¹² $K\alpha$ emission from a Ag signal layer was measured to estimate the effect of heating in a solid target via hot electrons. The target consists of CD, Mo, and Ag layers, whose thickness are 30, 50–300, and 50 μm , respectively. The 100 TW laser is irradiated from the CD side into the preproduced plasma at a laser intensity of 10^{19} W/cm^2 . An electron beam with a spectrum shown in Fig. 4 goes into the target and cause $K\alpha$ emission in the Ag layer. The Mo layer was used as the absorbing layer of the electron beam. The $K\alpha$ emission in Ag becomes possible with energy larger than 25.5 keV. Figures 5(a) and 5(b) show the results of the $K\alpha$ emission measurement, where the horizontal axis is the photon energy and the vertical the photon intensity (arbitrary unit) with and without the preproduced plasma. The data were recorded with an x-ray charge coupled device (CCD) with a photon counting mode. The absolute sensitivity of the CCD was calibrated with ^{55}Fe ($E_{K\alpha} = 5.9 \text{ keV}$) and

FIG. 4. Typical electron spectrum of ultra-intense laser shot into a preproduced plasma.

FIG. 5. $K\alpha$ emission spectra from (a) without plasma and (b) with a preproduced plasma. $K\alpha$ emissions from Ag signal layer were measured with an x-ray CCD.

^{109}Cd ($E_{K\alpha} = 22.2$ keV) and radiation sources. As shown in the figure, the level of Ag $K\alpha$ emission is about half for a case with a preproduced plasma compared to a case without plasmas. This tendency is reflected to the conversion efficiency. The thickness of Mo absorption layer was varied to estimate the electron temperature from the decay slope of the emission with increasing thickness. The experimental data have been compared to the simulation by our 2D PIC code. The suggested temperature is about 2 MeV and the conversion efficiency is 15%–20% for the case with the preproduced plasma.

C. Energetic ions

Ion acceleration may be possible subsequent to the hot electron generation. Once generated via ultra-intense laser, the ponderomotive force or quiver motion in the e -field hot electrons causes ion acceleration by the anomalous electrostatic field resulting from the charge separation. The mechanisms of the acceleration may be due to the electrostatic field created between the hot electrons and left over ions, ion reflection from the ion potential (Zagdeev potential) built up by the directly accelerated ions via the electrons, or Coulomb explosion.^{17–19} The acceleration direction of ions from the Coulomb explosion may be into 4π steradian or normal to the surface of the explosion, while the first and second mechanisms may cause the forward-directed ions.

The ion acceleration has been studied via the fusion process, which is caused by fast deuterium ions from ultra-intense laser plasma interactions colliding with deuterium within a solid target. Two time of flight detectors called “Mandala” were used as a single hit neutron detector with 421-elements each.²⁰ The detector element was calibrated using accelerator facility. The energy resolution is 30 keV for 2.5 MeV neutrons. Each Mandala was placed at 54.7° and 90° from the 100 TW laser axis, covering a solid angle of 20 msterad with a 3 m diam. When a CD_2 target of $60\ \mu\text{m}$ thickness was irradiated at a condition same as the super penetration shot described in Sec. II A, 2×10^5 DD neutrons are observed. More detailed studies of the neutron spectra have been conducted without preproduced plasmas, since less gamma ray noise is on the detectors without preproduced plasmas, resulting in much better S/N of the signals. Figure 6 shows one of those neutron spectra (a) at 54.7° and (b) 90° from a CD planar target of $5\ \mu\text{m}$ irradiated at 10^{19} W/cm^2 with a possibly 10^{-4} prepulse level compared to

the main laser intensity. When the accelerated ions move into a CD solid target, the fusion spectrum is affected according to the ion kinetic energy. The dominant process in our case is concluded to be due to $d^*(d,n)^3\text{He}$, after several calibration shots carefully conducted. The neutron energy spectrum can be shifted from 1.63 MeV to an upper limit determined by max ion energy. If the fusion process is exothermic and the spectrum is caused by a Doppler shift the neutron spectrum should be observed only above 1.63 MeV. The spectrum also depends sensitively on the observation angle (roughly with $\cos^2 \theta$). The neutron spectrum at 54.7° in Fig. 6(a) extends from 2 MeV to 4 MeV peaked at just above 2.5 MeV. The one at 90° in Fig. 6(b) extends similarly from 2 MeV to 3.5 MeV. The peak is at just below 2.5 MeV. The number of neutrons is 1.0×10^6 . The average energy of accelerated deuterons is estimated to be from 80 keV to 100 keV when a Monte Carlo simulation is used to fit the observed data. The distribution of the deuteron acceleration into the target is within the forward 2π hemisphere, slightly weighted toward the laser direction. Ion acceleration at a target backside has been studied using 2D (two-dimensional) PIC code simulation, as shown in Fig. 7. Here we note that the direction of the accelerated ions is normal to the target. In the simulation, a wedge shape target is used, whose sizes are $23\ \mu\text{m}$ the vertical direction and $13.5\ \mu\text{m}$ in the horizontal. The 100 TW, 0.2 ps laser pulse comes in from the left onto the target obliquely at 30° with the P polarization as shown in Fig. 7(a). The Roman number in Fig. 7(a) corresponds to the directions normal to each face of the wedge target. The target consists of electron plasma density of 4 times n_c . In Figs. 7(b) and 7(c) the accelerated ion flows are shown with a normalized momentum for both horizontal and vertical axes. Figures 7(b) and 7(c) correspond to time at 80 fs and 200 fs. Initially weak ion flows are observed normal to the target face normal directions. As time elapsed, much more energetic ion flows are observed normal to the target face as high as 4 MeV. Similar experimental results will be reported in Ref. 21. In the simulation hot electrons escaped from the target formed a electrostatic sheath, resulting in the ion acceleration normal to the target backside. Since the details of ion acceleration mechanisms will depend on the target thickness, target material, target shape, and laser polarization, further experimental studies will be called for.

D. First demonstration of a compressed core heated by short pulse self-focusing and hot electrons

We have reported ponderomotive-force self-focusing at 1 μm laser wavelength in plasmas with an overdense region with a 100 ps pulse at a vacuum focused laser intensity of 10^{17} W/cm 2 .⁷⁻⁹ We have learned that a whole beam self-focusing is formed in a plasma with a density scale length of 100 μm , producing hot electrons with an energy spectrum ranging from 100 keV to 1 MeV. As a summary, the self-focusing occurs when 1 μm laser is focused at close to the critical density in the preformed plasma at 10^{17} W/cm 2 laser intensity. The penetration depth of the whole beam self-focusing can be more than 200 μm in the plasma with an overdense region. Figure 8 summarizes our previous results. Figure 8(a) shows an interferogram picture of self-focused channel formation and cross sections in an underdense plasma. The interferogram was taken with an ultraviolet (UV) probe beam (wavelength, $\lambda=263$ nm; pulse width, $\tau=10$ ps) to show a whole beam self-focusing. The self-focused channel in an overdense region was observed with an x-ray laser probe ($\lambda=19.6$ nm, $\tau=80$ ps) to show the whole beam self-focusing channel in Fig. 8(b), where the density profile and the cross section of the density profile are presented. In the density profile, a straight channel formation is clearly shown. In the cross section, two small arrows indicate the width of the channel formation of about 30 μm . Figure 8(c) shows a time-integrated x-ray pinhole picture of

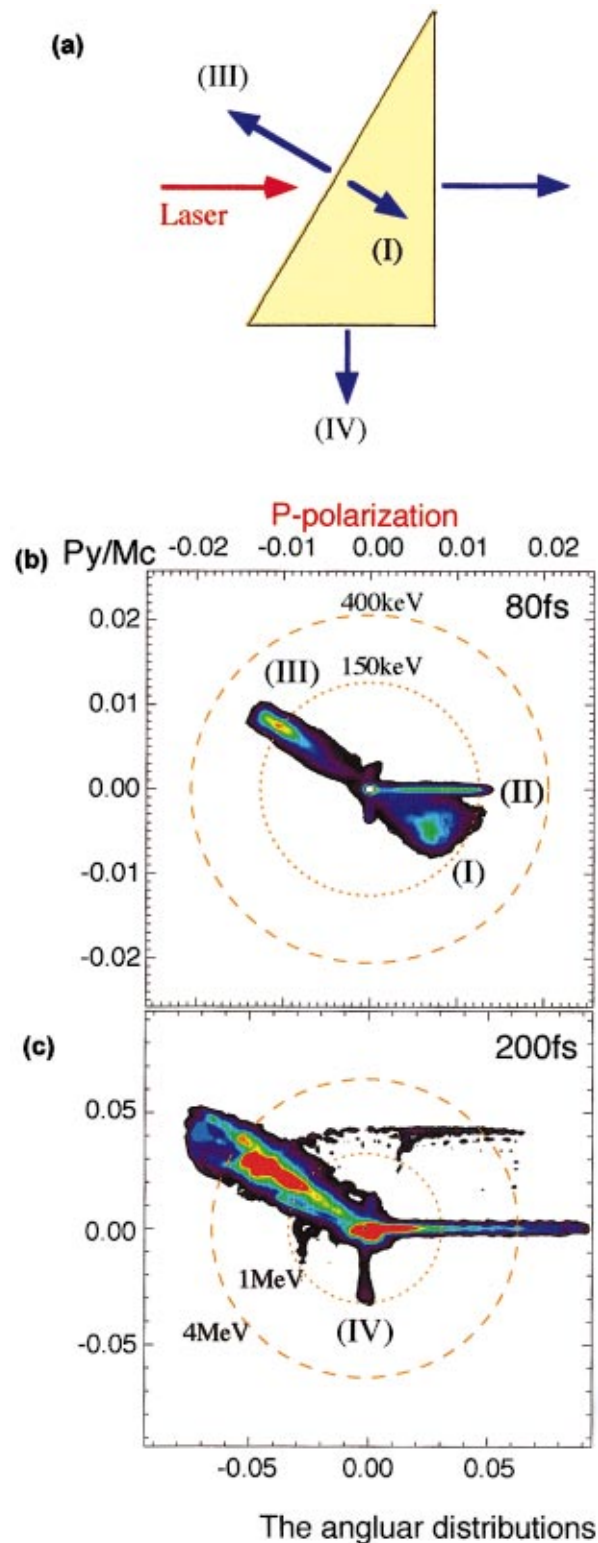

FIG. 7. (Color) Ions acceleration simulation for a wedge target. (a) Simulation set up, (b) ion acceleration at 80 fs, and (c) at 200 fs.

side and front views for the channel formation shot. The side-on x-ray picture shows a less than 30 μm emission spot at the surface of a planar target, indicating that the self-focused laser beam penetrated through the preformed plasma and reached the surface region. The front view shows the same local emission due to the self-focused pulse.

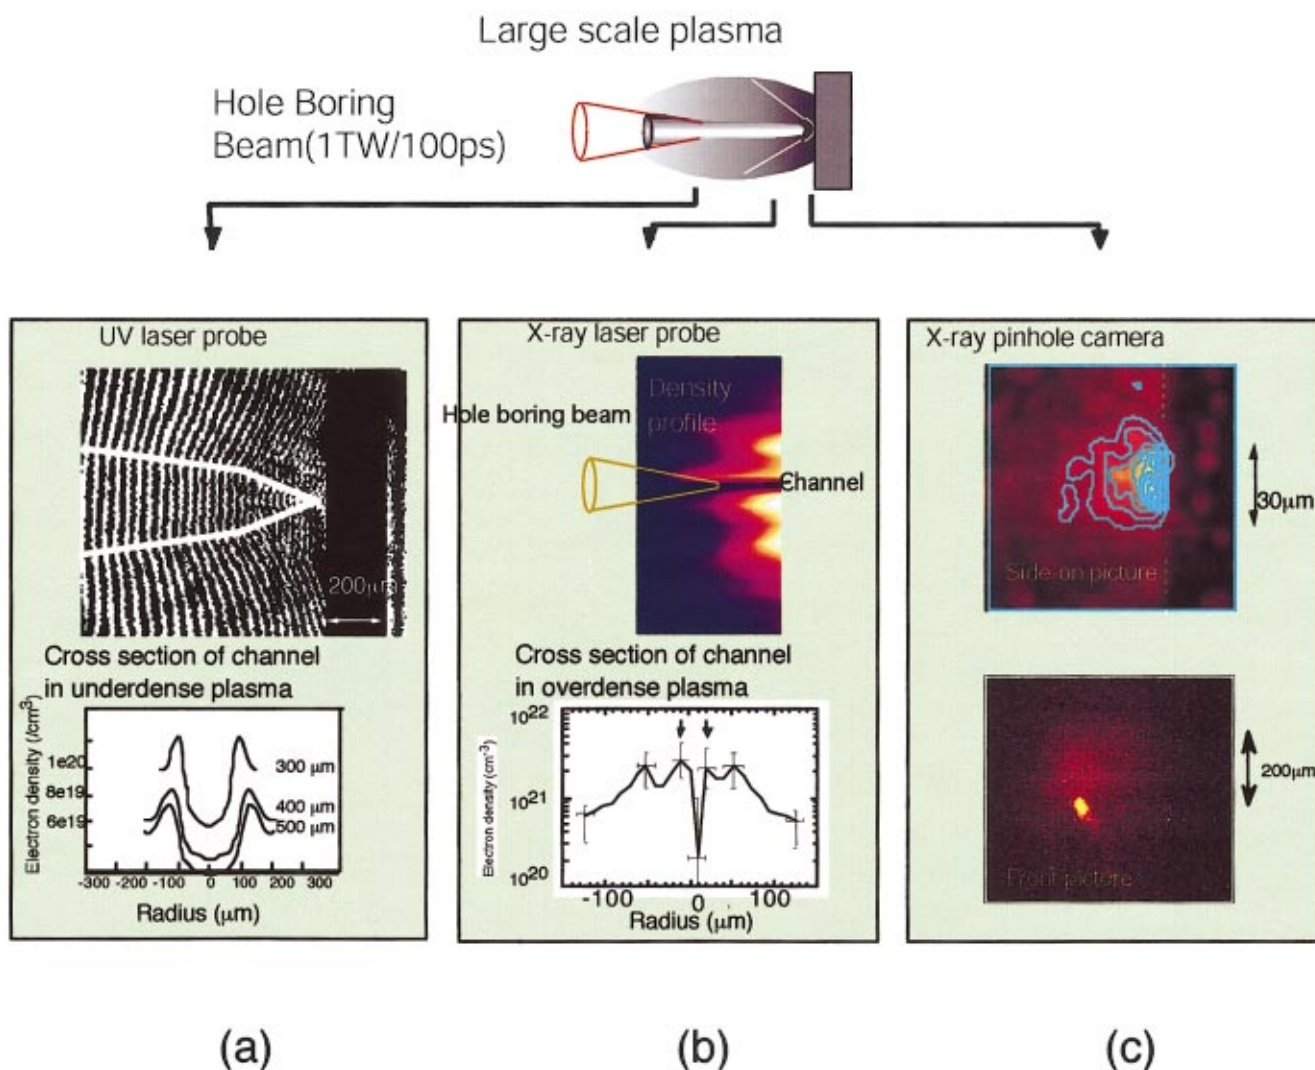

FIG. 8. (Color) Summary of whole beam channel in a plasma. (a) UV laser probe image and cross sections of self-focused channel in an underdense plasma; (b) x-ray laser probe image and cross sections of the channel in an overdense plasma, and (c) x-ray pinhole pictures of the channel.

Then we applied this type of self-focusing to an imploded core and tried to heat the core. It is very interesting to study how the whole beam self-focusing affects implosion cores or plasmas from the viewpoint of FI. In order to check this we have injected the 100 ps double pulses into implosion plasma. In order to satisfy the condition for a uniform implosion, we have to keep all twelve-laser beams of the GEKKO XII with a long pulse. For self-focusing and heating, we need laser beams with 100 ps pulses. The beam configuration applied in these shots is shown in Fig. 9. Each beam line of the GEKKO XII sends a 1 ns partially coherent (PCL) laser pulse followed by 100 ps double pulses with 150 ps time delay from the end of the PCL laser pulse. The 100 ps double pulses are separated by 300 ps. All the laser pulses are at 1 μm wavelength. The PCL pulse is known to have a very uniform focused pattern²² and to have a large beam divergence angle (120 μrad). Due to this beam divergence angle, the diameter of the far field pattern becomes 150 μm for PCL, while the normal laser (100 ps pulse) focuses down to 30 μm . Making use of this focusing difference, the PCL pulse could be used for imploding a shell first and the laser

pulses are used to self-focus and to heat the plasma. The CD shell of 193 μm diam with a 21 μm shell thickness was irradiated with the 12 beams of GEKKO XII. The total of 840 J PCL laser energy and 977 J first 100 ps pulse and 742 J second 100 ps pulse are delivered onto the target. The laser beam focus was set at 170 μm from the center of the target. ILESTA²³ 1D simulation result indicates that the density and ρR are 6 g/cm^3 and 0.018 g/cm^2 at the first 100 ps injection and are 18 g/cm^3 and 0.041 g/cm^2 , respectively, at the second. The core radius at the max compression (at the second 100 ps timing) is 30 μm .

Figure 10 shows the x-ray pinhole pictures of such shots. Figure 9(a) indicates a CD implosion result without 100 ps double pulses. The image shows weak x-ray emissions only from the initial shell diameter. The implosion is so weak that almost no x-ray emission comes from the core of 60 μm diam. Figure 9(b) indicates a strong ringlike emission coming from roughly a 100 μm diam. The additional 100 ps pulses caused this strong emission. The double pulse emissions were confirmed clearly also with x-ray streak and x-ray framing cameras. On this shot hot electrons with an energy

FIG. 9. Laser configuration used for implosion of a CD shell and subsequent core heating by 100 ps double pulses.

spectrum ranging from 100 keV to 1 MeV were also observed. This type of core heating will be an important subject for the near future experiments for FI and should be studied in detail. It should not be limited for fast ignition, such that a laser system in a reactor has only one fast ignition laser line. Each laser beam line can hold a long tailored pulse for implosion followed by short pulse(s) FI. Another advantage for multiple beams lines for fast ignition pulses could be that sending multiple pulses could avoid the Alfvén current limit and could transport a large amount of ignition energy to a imploded core.

IV. CONCLUSION

We have shown the laser interaction studies with a 1 ps at 10^{19} W/cm² and a 100 ps at 10^{17} W/cm² laser pulses. In the 10^{19} W/cm² experiments, a super penetration of laser pulse has been observed to penetrate in a plasma with a 100 μm density scale length and to reach the target surface. Over 1 MeV energy electrons are observed and are converted to heat a solid target with a 20% efficiency with the presence of the plasma. Energetic deuterons are also produced to cause a 10^6 D–D fusion product. The average accelerated ion energy is about 100 keV.

In the 10^{17} W/cm² experiment, a mode of whole beam self-focusing has been established in a preproduced plasma

and has been applied to an implosion plasma. The self-focused pulse could create 0.1–1 MeV hot electrons. A weak and relatively large implosion core was created and was heated by the self-focusing and heating pulses for the first time.
