(Received 13 April 2012; revised manuscript received 22 July 2013; published 30 August 2013)

The structure of the neutron-rich nucleus 58Ti was investigated via proton inelastic scattering in inverse kinematics at a mean energy of 42.0 MeV/nucleon. By measuring the deexcitation γ rays, three transitions with the energies of 1046(11) keV, 1376(18) keV, and 1835(27) keV were identified. The angle-integrated cross section for the 1046-keV excitation, which corresponds to the decay from the first 2+ state, was determined to be 13(7) mb. The deformation length δp,p′ was extracted from the cross section to be 0.83+0.22−0.20 fm. The energy of the first 2+ state and the δp,p′ value are comparable to the ones of 56Ti, which indicates that the collectivity of the Ti isotopes does not increase significantly with neutron number until N = 36. This fact indicates that 58Ti is outside of the region of the deformation known in the neutron-rich nuclei around N = 40.

I. INTRODUCTION

The shell structure as the basis of our understanding of the atomic nucleus has recently been found to change drastically due to the rearrangement of the single particle levels as one moves away from the stability line. In unstable nuclei with very asymmetric proton and neutron numbers, various exotic properties have been revealed such as the anomalous deformation emerging in the very neutron-rich regions around Z = 28, 60Ni shows small collectivity reflecting the magic character of N = 40 as indicated by its large value of the energy of the first 2+ state [Eg.s(2+)] and small value of quadrupole transition probability [B(E2)] [8,9]. However, in Fe isotopes (Z = 26), the Eg.s(2+) values start decreasing at N = 38, and this decrease continues monotonically beyond N = 40 [10,11]. This indicates that N = 40 does not exhibit a magic character in Fe anymore [12,13]. In the Cr isotopes (Z = 24), the enhancement of the collectivity is seen already in the nuclei with N = 36, where the Eg.s(2+) values drop much below the typical value of the open neutron-shell nuclei along the Cr isotopic chain [7,14]. The decrease continues until 56Cr, in which Eg.s(2+) value shows the smallest among the known Eg.s(2+) values in this region [15]. The enhancement of collectivity toward N = 40 in the Cr isotopes was confirmed by the rapid increase of deformation lengths (δ) and the Eg.s(4+)/Eg.s(2+) ratios (R4/2) [14,16]. A question arises as to whether the anomalous deformation region found in Fe and Cr isotopes further develops in more proton-deficient isotopes, in particular Ti.

Theoretically, a deformation region is predicted to appear around 62Ti [6]. Indeed, the enhancement of collectivity has been suggested for the Ti isotopes in this region from their β-decay half-lives. Approaching N = 40 from 58Ti to 60Ti, the β-decay half-lives become gradually longer than the shell model calculation within the pf shell, which is interpreted as being due to the admixture of the neutron v8g9/2 configuration [17]. Considering the deformation-driving nature of the v8g9/2 orbital, the increase of the v8g9/2 contribution would enhance the collectivity. To locate the boundary of the anomalous deformation region in the Ti isotopes, the study of the collectivity of Ti isotopes is of great importance.
We have investigated the properties of $^{58}$Ti, through the low-lying states including the first $2^+$ state, whose preliminary result was partially reported in Ref. [18]. We utilized the proton inelastic scattering in inverse kinematics to populate these states, which enables us to extract the $\delta$ value as well as the excitation energies. These two quantities [$\delta$ and $E_x(2^+_1)$] are essential for the discussion of the quadrupole collectivity. This measurement was possible even with a low-intensity beam due to the high efficiency and high signal-to-noise ratio of the measurement achieved by the use of the $\gamma$-ray spectroscopy technique incorporating a thick liquid-hydrogen target. In this paper, we report on the $\delta$ value and two new $\gamma$ transitions as well as the $E_x(2^+_1)$ value.

II. EXPERIMENT

The experiment was performed at RI Beam Factory operated by the RIKEN Nishina Center and Center for Nuclear Study, University of Tokyo, using the same experimental arrangement described in Ref. [14]. A cocktail beam composed of several nuclear species including $^{58}$Ti was produced by the fragmentation reaction of a $^{50}$Zn primary beam with a typical intensity of 150 p nA impinging on a 96-mg/cm$^2$ (0.52-mm) Be target at 63 MeV/nucleon. The fragments produced were collected and analyzed by the RIKEN projectile-fragment separator (RIPS) [19]. The particle identification (PID) of the cocktail beam was made on an event-by-event basis. The average intensity of $^{58}$Ti was 1.5 counts/s, while the total beam intensity was $1 \times 10^3$ counts/s.

A 72-mg/cm$^2$ thick liquid-hydrogen produced by the "cryogenic proton and alpha target system" (CRYPTA) [20] was bombarded by the secondary beam inducing excitation of $^{58}$Ti via proton inelastic scattering. The energy of $^{58}$Ti at the center of the secondary target was 42.0 MeV/nucleon.

The levels populated by the secondary reactions were identified by measuring the deexcitation $\gamma$ rays in coincidence with the reaction residues. The $\gamma$ rays were measured by DALI2 [21], which consisted of 160 NaI(Tl) scintillators surrounding the secondary target. The $\gamma$-ray energies were corrected for the Doppler shift using the angle between the scattered particle and the triggered crystal. The spectral shape and efficiency of $\gamma$ rays were obtained by a Monte Carlo simulation using the GEANT code [22]. The energy resolution and full-energy peak efficiency for 1046-keV $\gamma$ rays emitted from a moving $^{58}$Ti projectile were determined to be 8.5% (FWHM) and 18%, respectively.

The scattered particles were identified using the "TOF mass analyzer for RI beam experiments" (TOMBEE) [23] by measuring their TOF, $\Delta E$, and total kinetic energy ($E$). The atomic number $Z$ and the mass number $A$ were obtained from the TOF-$\Delta E$ and TOF-$E$ correlations with resolutions of 1.5% and 1.2% (FWHM), respectively. The good mass resolution of 1.2% enabled the unambiguous identification of the reaction residues in the medium-mass region around $A \sim 60$. The transmission of TOMBEE was evaluated by the ion optics code COSY INFINITY [24] to be about 90% at 0 degrees, decreasing with the scattering angle to 50% at 2 degrees. The total transmission integrated over the scattering angle is 88% for nonreacted events and 87% for inelastically scattered events.

III. RESULTS

The Doppler-shift corrected energy spectrum of $\gamma$ rays measured in coincidence with inelastically scattered $^{58}$Ti is shown in Fig. 1(a). Three peaks at 1046(11) keV, 1376(18) keV, and 1835(27) keV were clearly identified. The quoted errors include the statistical ones and uncertainties in the energy calibration. The energy of the 1046-keV peak is consistent with our earlier report [1046(17) keV] [18], while the error is reduced. The 1046-keV peak was observed most strongly, and was thus assigned to the transition from a newly identified first $2^+$ state to the $0^+$-ground state.

In the $\gamma$-ray spectrum gated on the 1046-keV peak shown in Fig. 1(c), the $\gamma$ line at 1835 keV is observed. This transition was therefore assigned to be the one from a level at 2881(33) keV to the first $2^+$ state as illustrated in Fig. 2. In the region around 1376 keV, two events are observed, which correspond most probably to the full-energy peak of the 1376-keV $\gamma$ rays observed in coincidence with the $2^+ \rightarrow 0^+$ transition. It is less likely that these events are due to coincidence with the Compton scattering of the 1835-keV $\gamma$ rays, since the probability of observing more than two events due to such a process is estimated to be 18%.

The angle-integrated cross section for the direct excitation to the first $2^+$ state in $^{58}$Ti was obtained from the peak yield of

![Fig. 1](https://example.com/figure1.png)
The $2^+_1 \rightarrow 0^+_1$ transition with the $\gamma$-ray multiplicity equal to 1 (denoted $M = 1$ hereafter) as shown in Fig. 1(b). The peak yield was extracted by fitting the spectrum with the sum (solid curve) of the response function of DALI2 for the $2^+_1 \rightarrow 0^+_{gs}$ transition (dashed curve) and an exponential background (dotted curve). The condition of $M = 1$ was intended to eliminate the $2^+_1 \rightarrow 0^+_{gs}$ transitions which is accompanied by cascade emission of $\gamma$ rays from higher excited states. Because of the high total detection efficiency of $\gamma$ rays ($\sim 70\%$), most of the cascade events were eliminated by this condition. The contamination by the cascade events in the $M = 1$ spectrum was estimated to be 22\% by the Monte Carlo simulation and was corrected for. It was found that the contributions of the direct excitation to the first $2^+$ state amount to 34(16)\% of the observed $2^+_1 \rightarrow 0^+_{gs}$ transition.

The first $2^+$ excitation cross section was determined to be 13(7) mb, after correcting for the transmission and the $\gamma$-ray detection efficiency. The quoted error includes the statistical one (31\%), and the uncertainties in the target thickness (5\%), the $\gamma$-ray detection efficiency (4\%), and the cascade subtraction (16\%).

In order to extract the deformation length $\delta_{p,p'}$, the calculations based on the distorted-wave theory were performed using the ECTIS97 code [25]. The collective vibrational model was adopted with four sets of optical potential parameters [26–29]. The average for $\delta_{p,p'}$ is $0.83^{+0.22}_{-0.30}$ fm. The error includes the uncertainty of the experimental cross section and the one due to the choice of the potential parameters (4\%). The corresponding deformation parameter $\beta_2(=\delta_{p,p}/R)$ is $0.18^{+0.05}_{-0.03}$ using the nuclear radii given by $R = r_0A^{1/3}$ ($r_0 = 1.2$ fm).

IV. DISCUSSION

The $E_x(2^+_1)$ value of $^{58}$Ti obtained in this work is compared with those of the lighter even-even Ti isotopes in Fig. 3(a) (circles). The $E_x(2^+_1)$ value of $^{58}$Ti is slightly smaller than that of $^{56}$Ti, but is not significantly smaller than those of the lighter open-neutron-shell Ti isotopes. This indicates that the collectivity is not particularly enhanced in $^{58}$Ti with $N = 36$. Therefore, $^{58}$Ti is outside of the region of large collectivity known in the Fe and Cr isotopes close to $N = 36$. The region of large collectivity emerges in the Fe isotopes from $N = 38$ [Fig. 3(a) (squares)], and then develops further in the Cr isotopes [Fig. 3(a) (triangles)] in a wider region starting from $N = 36$. Our finding shows that the region of large collectivity is not extended to the Ti isotopes at $N = 36$ as in the Cr isotopes. The slight decrease of the $E_x(2^+_1)$ value in $^{58}$Ti could be a precursor of the drop in more neutron-rich isotopes due to a possible enhancement of collectivity.

The experimental values were compared with the results of the shell model calculation within the $pf$ shell using the GXPF1A interaction [30–32] in Fig. 3(a). In the Ti isotopes, the $E_x(2^+_1)$ values obtained with the calculation show an overall agreement with the experimental values including the one for $^{58}$Ti. For the neighboring isotopes, the calculation deviates from the experimental $E_x(2^+_1)$ values beyond $N = 38$ in the Fe isotopes and beyond 36 in the Cr isotopes. In this region, the experimental values start decreasing, while the theoretical values remain almost constant and then increase at $N = 40$. The deviation in Fe and Cr isotopes indicates that the $pf$-shell model space is not sufficient to describe these nuclei, and that the contribution of the $g_{9/2}$-shell configuration has to be considered [14,33]. The good agreement between the experimental and theoretical $E_x(2^+_1)$ values in $^{58}$Ti demonstrates that the contribution of the $g_{9/2}$ shell is not significant in this nucleus.

The $\delta_{p,p'}$ value of $^{58}$Ti is plotted in Fig. 3(b) (filled circle) along with the ones for the stable Ti isotopes, $^{46,48,50}$Ti and $^{56,58,60,62,64}$Ti.
the valence protons partially fill the competition between the following two effects. One is that 36 isotonic chain shows that the collectivity increases from shell is filled. The experimental 58Ti is about the same as that of 56Ti within the experimental distribution, while significant at 58Ti.

The behavior of the collectivity in the nuclei in this region could be qualitatively understood as the result of competition between the following two effects. One is that the valence protons partially fill the πf1/2 shell, which favors deformation [34]. The other is narrowing of the energy spacing at N = 40 between vF3/2 and vG9/2 by the strong proton-neutron interaction [7,30–32]. The monopole component of the proton-neutron interaction is attractive between πf1/2 and vF3/2, and repulsive between πf1/2 and vG9/2. When protons are removed from the πf1/2 orbital, vF3/2 is shifted upward and vG9/2 is shifted downward, resulting in the narrowing of the energy spacing between vF3/2 and vG9/2. The latter effect should increase monotonically as number of protons in πf1/2 decreases from Ni down to Ca. On the other hand, the former effect should increase in the beginning, but would start decreasing beyond the Cr isotopes in which half of the πf1/2 shell is filled. The experimental Eπ(2+)(N) values along the N = 36 isotonic chain shows that the collectivity increases from 64Ni to 60Cr, and then decreases in 58Ti. This behavior suggests that the former effect is stronger than the latter in the N = 36 isotones. Approaching N = 40, the balance between these two effects may change. The mechanism of the deformation in the neutron-rich pf-shell nuclei should be revealed by studying the evolution of the collectivity in a wider region of nuclei.

V. SUMMARY

In summary, we have investigated the structure of the neutron-rich nucleus 58Ti via proton inelastic scattering in inverse kinematics at a mean energy of 42.0 MeV/nucleon. By measuring the deexcitation γ rays, three transitions with energies of 1046(11) keV, 1376(18) keV, and 1835(27) keV were identified. The energy of the 1046-keV peak, which corresponds to the first 2+ state, is consistent with our earlier report [18]. The 1376-keV and 1835-keV transitions were assigned as the ones from the levels at 2422(22) keV and 2881(33) keV to the first 2+ state, respectively, where the former assignment is a tentative one. The angle-integrated cross section for the excitation to the first 2+ state was determined to be 13(7) mb. The deformation length δp,p was extracted from the cross section to be 0.83±0.22 fm. The Eπ(2+) value and the deformation length of 58Ti are comparable to the ones of 56Ti. These values indicate that the collectivity of the Ti isotopes does not change significantly with neutron number until N = 36, which is in contrast to the Cr isotopes whose collectivity starts increasing at N = 36. This fact indicates that 58Ti is outside of the region of the deformation known in the neutron-rich nuclei around N = 40. From the comparison to a shell model calculation, 58Ti is found to be well described within the pf-shell model space.

ACKNOWLEDGMENTS

We thank the RIKEN Ring Cyclotron staff members for providing the stable primary beam throughout the experiment. We would like to thank Dr. M. Honma for fruitful discussions. One of the authors (H.S.) would like to acknowledge support from a research grant of the Japan Society for the Promotion of Science.
