SUMMARY

Background: There is no current way to determine the actual blood and body fluid exposure (BBFE) incidence in hospitals. We propose a simple, reliable, and widely available method for the accurate estimation of BBFE.

Methods: Data for BBFE for healthcare workers between 2006 and 2015 at Osaka University Hospital were retrospectively extracted from the electronic records. Annual positivity of hepatitis C virus (HCV) antibody in the source individuals and overall patient population were calculated over time. We created an estimation formula focusing on the difference in HCV positivity between the source individuals and overall patient population for the actual number of BBFEs. A linear regression model was used to evaluate the temporal change in the reported and estimated BBFEs.

Results: During the study period, 937 BBFEs were reported. HCV positivity between the post-BBFE cohort and overall patient population greatly differed; the incidence ratio ranged from 2.1 to 5.7. The linear regression model revealed that the reported BBFEs did not significantly change during the study period (the slope, 1.315 [95% confidence interval (C.I.): -0.849 to 3.480, $p = 0.199$]). The annual incidence ratio of the estimated and reported BBFEs significantly reduced over time (the slope, -0.287 [95% C.I.: -0.488 to -0.086, $p = 0.011$]), indicating that, although the reported number of BBFEs seemed unchanged, the estimated incidence decreased.

Conclusions: We propose a novel and simple approach to estimating the actual incidence of BBFEs in hospitals using the difference in HCV positivity between the post-BBFE cohort and overall patient population.

KEY WORDS

blood and body fluid exposure, healthcare worker, hepatitis C virus, occupational infection control prevention

INTRODUCTION

Blood and body fluid exposure (BBFE) during daily hospital routines is inevitable for health-care workers (HCWs) [1], despite the development of safety-engineered devices and accumulated knowledge for preven-

tion [2]. According to the World Health Organization, the annual global incidence of percutaneous BBFE in HCWs is as high as 3 million [3]. Although the major concerns as a consequence of BBFE are hepatitis B virus (HBV), hepatitis C virus (HCV), and human immunodeficiency virus (HIV) infections [4], more than 50 blood-borne pathogens can cause infections after BBFE [5].

Based on the US General Accounting Office, follow-up expenses, excluding treatment, for HCWs after BBFE are > \$500 per incident [6]. In addition to the financial issues, occupational exposure results in emotional distress. Thus, a systematic approach for the prevention of BBFE is expected in hospitals.

Comprehension of the true incidence of BBFE is of great importance for infection control practitioners to evaluate their activities for the prevention of occupational exposure and to develop appropriate preventive strategies. Although HCWs are generally supposed to report a BBFE incidence to infection control services, the number of reported BBFE is almost without exception less than that of true events [7]. Namely, it is almost impossible to determine the actual number of BBFEs because of under-reporting [5,8-11]. For example, more than 80% of syringe injuries were unreported in Taiwan before 2000 [12,13]. Understandably, the reported BBFEs may only be the tip of the iceberg, and a decrease in the number of reported BBFEs does not accurately reflect a true reduction in the hospital. No gold standard to estimate the actual incidence of BBFE exists, and all previous interventional or observational studies concerning BBFEs have been merely based on the reported number, which could under-represent the actual incidence [14-16].

In this study, we propose a novel, simple, and widely available estimation formula that uses HCV positivity in a post-BBFE cohort and the overall patient population in hospitals. Using this approach, we estimated the actual incidences of BBFEs in our university hospital for the last 10 years and evaluated the difference between the reported and estimated numbers of BBFEs.

MATERIALS AND METHODS

This study was conducted at Osaka University Hospital, a 1086-bed tertiary care academic facility in Japan. Data, including the nature of the injury and occupation, for HCWs with BBFE between 2006 and 2015 were extracted from the electronic database of the Infection Control Service and Clinical Laboratory. All BBFEs were registered in the Exposure Prevention Information Network, Japan. The study protocol was approved by the Institutional Review Board of Osaka University Hospital (No. 10105-2). The need for informed consent was waived because we retrospectively collected data without the use of any individually identifying information or the application of any intervention.

In our hospital, we measure seropositivity of the source individuals for HBV (antigen/antibody), HCV (antibody), HIV (antigen/antibody), human T-cell leukemia virus type 1/2 (antibody), and syphilis (rapid plasma reagin) using blood samples submitted immediately after BBFE events to clearly determine the infectious profile at the time of exposure. Of these, we collected data for HCV positivity in the source individuals. Also, the annual HCV positivity of the overall patient population at our facility was calculated. If HCV antibody was measured ≥ 2 times within a year for an individual, only one of the measurements was included. The HCV antibody was measured using the Architect i2000 Analyzer (Abbott Japan Co., Ltd Tokyo, JAPAN).

Our estimation formula consists as follows;

- i the number of reported BBFEs
- ii the number of reported BBFEs by an unknown source
- iii HCV positivity of source individuals in the post-BBFE cohort, and
- iv HCV positivity in the overall patient population

Estimated incidence of BBFEs = [(i) - (ii)] \times $\frac{\text{(iii)}}{\text{(iv)}}$ + (ii)

We focused on the difference in HCV positivity between the post-BBFE cohort and overall patient population. Theoretically, a BBFE occurs randomly regardless of HCV positivity, and the positive rate in the post-BBFE cohort should be comparable with that in the overall patient population. However, the HCV positivity of the source individuals in the post-BBFE cohort was much higher than that in the overall patient population, potentially because of the under-reporting of BBFE events. For instance, when a HCW experiences a BBFE with an HCV-positive source individual, he or she presumably reports the exposure to the Infection Control Service. However, with an HCV-negative source, the incidence may not be reported. With fewer reports of BBFEs with HCV-negative sources, the HCV positivity in the post-BBFE cohort would be higher. Thus, in the estimation formula, we calculated the ratio of HCV positivity in the post-BBFE cohort to that of the overall patient population and multiplied it by the number of source-apparent BBFEs.

Statistical analysis was performed using EZR software, which is a modified version of R Commander (version 2.2-5) based on R (version 3.3.1) [17]. We defined the annual incidence ratio as the ratio of the estimated BBFEs to the reported BBFEs in a year. We applied a linear regression line of this ratio to evaluate the difference in the annual incidence between the reported and estimated BBFEs over time. Statistical significance was calculated by comparing the regression line to a zero line. A p-value < 0.05 was considered statistically significant.

* - Forceps, glass ampoules, wires, etc., ** - Nurse's aides, students, patients, and unknown cases.

Table 2. Annual Hepatitis C virus (HCV) positivity in the post-blood and body fluid exposure (BBFE) cohort and overall patient population.

	2006	2007	2008	2009	2010	2011	2012	2013	2014	2015
Post-BBFE cohort	35.1% (81)	27.2% (94)	36.1% (91)	22.4% (82)	17.4% (97)	22.9% (80)	20.7% (102)	18.2% (105)	13.8% (87)	10.2% (98)
Overall patient population	6.0% (11821)	5.7% (12071)	5.9% (12260)	4.9% (11786)	5.4% (11822)	4.8% (12429)	4.4% (12326)	4.4% (13119)	4.5% (13170)	4.6% (14180)

Overall patient population includes both in- and outpatients. The annual numbers of cases in which HCV antibody were measured are shown in parenthesis.

RESULTS

During the study period, a total of 937 BBFEs were reported to the Infection Control Service, including 740 needle injuries (79.3%), 54 sharp injuries (5.7%), 76 mucocutaneous exposures (8.0%), 23 unknown events (2.6%), and 44 others (4.7%). By occupation, medical doctors (388, 41.7%), nurses (456, 48.6%), laboratory technicians (31, 3.3%), service staff (35, 3.8%), and others (27, 2.9%) were affected (Table 1). HCV antibody was examined in 917 of the 937 BBFE events (97.9%). The annual HCV positivity between the post-BBFE cohort (10.2 - 35.1%) and overall patient population (4.4 - 6.0%) greatly differed (Table 2).

Figure 1 shows the numbers of reported and estimated BBFEs in each year using the estimation formula, as well as their ratios over time. The linear regression model revealed that the reported number of BBFEs did

not change significantly during the study period (the slope, 1.315 [95% confidence interval (C.I.): -0.849 to 3.480, $p = 0.199$]). However, the annual incidence ratio declined significantly (the slope, -0.287 [95% C.I.: -0.488 to -0.086, $p = 0.011$]).

DISCUSSION

In this study, we proposed a novel estimation formula to determine the actual number of BBFEs by focusing on the difference in HCV positivity between the source individuals in a post-BBFE cohort and the overall patient population. HCV is an RNA mono-stranded enveloped virus that has a wide distribution, infecting 2 - 3% of the world population [18]. For instance, in Japan, the HCV prevalence in the general population is reportedly 1.0 - 1.9% [19]. In the United States, 2.7 million per-

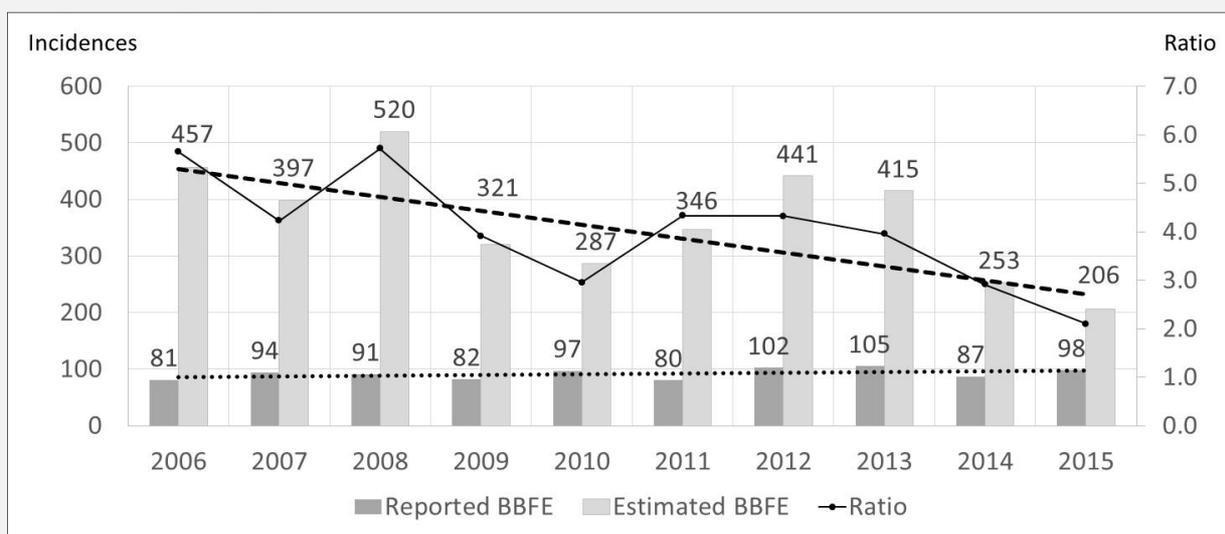

Figure 1. Annual reported and estimated blood and body fluid exposure (BBFE) incidents and the annual incidence ratio.

A solid line indicates the ratio of estimated BBFEs to reported BBFEs (annual incidence ratios). Bold and fine dotted lines are linear regression lines of the annual incidence ratio and reported number of BBFEs, respectively. The annual incidence ratio decreased significantly over time ($p = 0.011$), while the reported number of BBFEs did not.

sons, accounting for approximately 0.9% of the total population, have chronic HCV infection [20]. Thus, our equation provides a widely available method for infection control practitioners to practically estimate the actual incidence of BBFEs in their facilities.

Implementation of effective infection control strategies can reduce the transmission risk of viral hepatitis and HIV [21], and many preventable measures for BBFEs have been developed. However, BBFEs might not be reported properly; among the various occupations in hospitals, for instance, medical doctors are less likely to report BBFEs to the responsible sections than other HCWs [22]. Thus, poor reporting systems may provide incorrect estimates. The result of statistical analysis showed that the reported number of BBFEs remained at a constant level, while the estimated incidence tended to decline over time at our facility. These results can support the effectiveness of preventive measures for BBFEs in our hospital and the ability of our simple approach to offer an objective evaluation of the actual incidence of BBFEs.

The strength of this study is the accurate data for HCV positivity in the source individuals. Because of additional costs, previous data for infectious profiles have been applied for post-BBFE evaluation in many hospitals, although past data do not necessarily reflect the current status. For more than 10 years, we have required the known source individuals to submit their blood sam-

ples following BBFE events to understand their infectious profiles. Therefore, the HCV positivity of the present post-BBFE cohort is reliable.

HBV cannot replace HCV in the estimation formula. Although the HBV vaccination policy may differ in each medical facility or country, the proportion of HCWs vaccinated for HBV is higher than that in the general population. Thus, measurement of HB antibody is not useful for the estimation. Data for other HBV-related antigens or antibodies are usually not as frequently measured in the overall patient population and cannot provide a reliable adjustment. In contrast to HBV, vaccination for HCV has not been established [23], and this disadvantage turned out to be a strength for our method. The prevalence of HIV is still lower in Japan than in other countries, and its positivity is not applicable for the estimation. However, it may be possible to apply HIV positivity to our estimation formula in particular regions where HIV prevalence is comparatively high. Compared to the general population [19], HCV positivity at our facility was relatively higher, ranging from 4.4% to 6.0%. Hospitalized and ambulatory patients are usually older than the general population. Also, patients with HCV infection have been referred to our hospital because of its provision of tertiary care.

Several limitations of this study should be mentioned. First, the absence of a gold standard reference for the actual BBFE incidence should be noted. However, no

matter how much time passes, it is impossible to determine the actual number because of under-reporting. Second, the implementation rates of HCV serology among the overall patient population may influence the accuracy of the estimation. Less measured in the overall population, the HCV positivity, which is a denominator in the estimation formula, can vary. In Japan, HCV antibody is generally tested when patients are hospitalized or undergo surgeries. Therefore, we consider the HCV positivity of overall patient population in this study is comparatively reliable. Third, the nature of a single facility study might affect the generalizability of our methodology. Also, comparison of the estimated number of BBFEs among medical facilities may be difficult because of the different hospital characteristics.

CONCLUSION

We proposed a new, simple estimation formula for the estimation of the actual incidence of BBFEs using the difference in HCV positivity between the post-BBFE cohort and overall patient population. The reported number does not necessarily reflect the true incidence of BBFEs in each medical facility, while our method can provide a reliable estimation. By following the trend in the estimated number, it is possible to better comprehend and evaluate the real occurrence of BBFEs at each facility. In our facility, although the reported incidence of BBFEs did not change, the estimated incidence significantly decreased during the study period. Under-reporting of BBFEs continues to persist. A better understanding of BBFE occurrence in each medical facility can lead to appropriate evaluations and countermeasures for preventable BBFE.
