Clathrate hydrate; Phase equilibria; Raman spectroscopy; Structural transition

ABSTRACT

The three-phase equilibrium curves of hydrate, aqueous, and gas phases in the ternary system of

ethane (C₂H₆), ammonium bromide (NH₄Br), and water were measured at pressures up to 3 MPa and

temperatures of 278.45 to 283.76 K. The phase equilibrium curves exhibit two trends; the curve

paralleled with that of simple C₂H₆ hydrate and the one steeper than that of simple C₂H₆ hydrate.

The latter implies the incorporation of NH₄Br into C₂H₆ hydrate while the former indicates the

thermodynamic inhibition effect of NH₄Br. To investigate the incorporation of NH₄Br, Raman

spectra of the N–H stretching vibration of NH₄⁺ were analyzed. Raman spectra imply the existence

of the motionally restricted NH₄⁺ in the formed hydrate. Both results from the phase behavior and

Raman spectra imply the formation of C₂H₆+NH₄Br semi-clathrate hydrates.

1

1. Introduction

Clathrate hydrate is an inclusion compound, which has an ice-like appearance. Guest species like light hydrocarbons and noble gases construct clathrate hydrates with host water molecules. There are several kinds of hydrate cages and a couple of them are combined to form specific hydrate structures. The structure-I (sI) hydrate consists of two 5¹²-cages (pentagonal dodecahedron, hereafter called S-cages) and six 5¹²6²-cages (M-cages) in the unit lattice. In the same manner, the structure-II (sII) hydrate is formed with sixteen S-cages and eight 5¹²6⁴-cages (L-cages). Crystal structures and thermodynamic stabilities of gas hydrates mainly depend on the kind of guest species [1]. The familiar guest species for the sI hydrates are methane (CH₄), carbon dioxide (CO₂), ethane (C₂H₆). The CH₄ and CO₂ molecules are able to occupy both S- and M-cages [1-5]. The C₂H₆ molecule, whose molecular size is slightly larger than the void size of S-cage, occupies only the M-cages at pressures lower than approximately 20 MPa, while high pressures enable the occupancy of the C₂H₆ molecule in S-cages as well as M-cages [6].

Besides the regular clathrate hydrates, tetraalkyl ammonium or phosphonium salts with water form semi-clathrate hydrates [7-9]. Nitrogen or phosphorus atom as well as anions forms the hydrogen-bonded frameworks with water molecules. Shimada et al. [10] have reported the isobaric phase equilibrium (temperature–composition) relations for the tetra-*n*-butyl ammonium bromide (TBAB) semi-clathrate hydrate, one of the most famous substances forming semi-clathrate hydrates. The maximum equilibrium temperature of TBAB semi-clathrate hydrate at an atmospheric pressure with the TBAB aqueous solution (mass fraction of TBAB is 0.405) is 285.15 K.

Ammonia (NH₃) molecule, only from the viewpoint of molecular size, would be able to occupy the hydrate cages because its size is similar to that of CH₄. In fact, the previous studies [11-14] revealed that the water molecules form a dodecahedron cage (similar to S-cage) around NH₃ and ammonium ion (NH₄⁺) in the gas phase. However, it had been believed that NH₃ does not form clathrate hydrates and behaves as a thermodynamic inhibitor to the clathrate hydrate formation [15,16]. Instead of clathrate hydrate formation, NH₃ hemihydrate (2NH₃·H₂O), NH₃ monohydrate

(NH₃·H₂O), and NH₃ dihydrate (NH₃·2H₂O) form at high pressures around 10 GPa (at room temperature) [17,18]. Shin et al. [19] reported the NH₃ clathrate hydrates (simple NH₃ hydrate, CH₄+NH₃ mixed hydrate, and tetrahydrofuran+NH₃ mixed hydrate) at low temperatures and the location of the NH₃ molecules in the hydrate crystal was estimated based on the results from molecular simulation.

In the present study, we have investigated whether ammonium salts, instead of the NH_3 molecule, are possible to be enclathrated under the coexistence of ethane (C_2H_6) as a hydrate former. The thermodynamic stability boundary of the clathrate hydrates formed in the ternary system of C_2H_6 +ammonium bromide (NH_4Br)+ H_2O was measured. Not only the possibility of the enclathration of NH_4 + (also from the Raman spectra) but the effects of NH_3 and NH_4 + on the thermodynamic stabilities were discussed.

2. Experimental

2.1. Apparatus

The pressure-proof glass cell (Taiatsu Techno, HPG-10-1) (inner volume: 10 cm³, maximum working pressure: 5 MPa) was used for the phase equilibrium measurements. The experimental setup is the same as the one used previously [20,21]. The glass cell was immersed in the water bath where the temperature was controlled with the thermocontroller (Taitec, CL-80R). The equilibrium temperature was measured with the thermistor thermometer (Takara, D632, reproducibility: 0.02 K). The equilibrium pressure was measured with the pressure gauge (Valcom, VPRT, maximum uncertainty: 0.01 MPa).

2.2. Procedure

The NH₄Br (molar ratios of NH₄Br to H₂O are 1/35 ($x_{NH4Br} = 0.028$, $w_{NH4Br} = 0.134$) and 1/23 ($x_{NH4Br} = 0.042$, $w_{NH4Br} = 0.191$)) and NH₃ (molar ratios of NH₃ to H₂O are 1/35 ($x_{NH3} = 0.028$, $w_{NH3} = 0.026$), and 1/23 ($x_{NH3} = 0.042$, $w_{NH3} = 0.040$)) aqueous solutions were prepared with the

electric balance (Shimadzu BL-220H, maximum uncertainty is 0.004 g), where x and w stand for the mole fraction and mass fraction, respectively. A desired volume (each is approximately 2 cm³) of NH₃ or NH₄Br aqueous solutions was introduced into the glass cell and degassed by a freezing method. The contents were pressurized with C₂H₆ up to a desired pressure. A magnetic stirrer was moved up and down by a permanent magnet outside for agitation of the gas-liquid interface as well as the contents. The up-and-down agitating is quite important for supplying a sufficient amount of C₂H₆ in to the aqueous solution through the gas—aqueous interface. The contents were cooled and agitated to generate mixed hydrates. After the hydrate formation, the system temperature was increased by 0.1 K step every 3 hours. When the disappearance of the last hydrate particle was confirmed, we determined that the system reached a three-phase equilibrium condition of H+L₁+G (H: hydrate phase, L₁: aqueous phase, G: gas phase) with a desired composition of NH₃ or NH₄Br in the aqueous solution. After the complete dissociation of the formed hydrates, the system temperature was increased by 0.1 K step every 3 hours. We confirmed the change of the slopes of the fitting curves before and after the complete dissociation.

For the Raman spectroscopy, the quenched NH₄Br aqueous solution (molar ratio of NH₄Br to H₂O was 1/35) was grained in the mortar immersed in liquid nitrogen. The powder with approximately 200 µm in diameter was loaded into the high-pressure cell and then pressurized up to 1.7 MPa with C₂H₆. The sample was prepared at temperatures of 267 K in a temperature-controlled chamber (ESPEC, SU-241) for a couple of days. Just 1 hour before the Raman analysis, the sample in the cell was moved to a cold room and kept at 253 K there. The pressure in the cell was then released and allowed to reach atmospheric pressure. Once released, the sample was kept at 77 K. A laser Raman microprobe spectrometer with a multichannel CCD detector (JASCO, NRS-1000) was used. The Diode Pumped Solid State (DPSS) laser (Cobolt, Fandango) was irradiated to the samples at atmospheric pressure and 77 K. The backscatter was taken in with same lens. The wavelength of the DPSS laser was 514.5 nm and the output power was adjusted to 100 mW. The spectral resolution of the obtained Raman spectra was approximately 1 cm⁻¹.

2.3. Materials

C₂H₆ (molar purity: 0.999) was purchased from Takachiho Trading Co., Ltd. Guaranteed research grade aqueous NH₃ solution with 28 mass%(NH₃) was obtained from Nakalai Tesque. NH₄Br (molar purity: 0.990) and distilled water were purchased from Wako Pure Chemical Industries, Ltd. All materials were used without further purification.

3. Results and discussion

The three-phase equilibrium relations of the ternary system of C₂H₆+NH₄Br+H₂O were shown in Figure 1 and listed in Table 1. As shown in Figure 1, two trends of phase behavior were observed in each NH₄Br mole fraction. One (closed circles and squares) is the curve (blue) paralleled with that of the simple C₂H₆ hydrate [22, 23], the other (open circles and squares) is the curve (red) steeper than that of the simple C₂H₆ hydrate in the pressure-temperature diagram. The pressure and temperature relations of the simple C₂H₆ hydrate are correlated by the following equation:

 $ln(p/p_0) = a + bT$, where $p_0 = 1$ MPa. (1)

The above equation is superior to two-parameter Clausius-type equation. The constants a and b in the simple C₂H₆ hydrate system are -38.504 and 0.13793 K⁻¹ (the correlation coefficient r is 0.99787), respectively. The blue curves were drawn with the same b value in eq. (1). The drawn curves are fitted with the measured data. The values a (and r) in the NH₄Br/water molar ratios of 1/35 and 1/23 are -38.106 (r = 0.93665) and -37.994 (r = 0.49159), where the r value is due to insufficient number of datum sets), respectively.

In the former (parallel and blue curves), NH₄Br plays a role as a thermodynamic inhibitor for sI simple C₂H₆ hydrate formation, because the parallel shift of three-phase equilibrium curve is one of the most characteristic features for the thermodynamic inhibition using salts [1,24,25]. Moreover, no Raman signal derived from NH₄Br was detected in the formed hydrates. The latter (steeper and red curves) implies the possibility of the incorporation of NH₄Br to the clathrate hydrate. When the

experimental datum sets (open squares) in the NH₄Br/water molar ratios of 1/35 are correlated with the eq. (1), the slope b was 0.22423 K⁻¹ (r = 0.99367), which is larger than 0.13793 K⁻¹ of the simple C_2H_6 hydrate system. Both steeper curves at the NH₄Br/water molar ratios of 1/35 and 1/23 have similar slope in the pressure-temperature projection. In the case of the molar ratio of 1/35, two curves intersect at 282.4 ± 0.1 K and 2.31 ± 0.04 MPa. Also in the case of the molar ratio of 1/23, the intersection would be located around 278.5 ± 0.2 K and 1.8 ± 0.1 MPa. The intersections are structural transition points. At temperatures higher than the points, the simple C_2H_6 hydrate phase is thermodynamically stable, while the $C_2H_6+NH_4Br$ hydrate is under metastable state. The symbols (m) in Table 1 represent the data under metastable conditions. The data scatter in the system with the molar ratio 1/23 would be due to the metastability.

To investigate the incorporation of NH₄Br to the hydrate formation, Raman spectra for the hydrates prepared at a temperature below the structural transition point in the ternary system of C₂H₆+NH₄Br+water were measured. Raman spectra of the C-C stretching vibration of the C₂H₆ molecule are shown in Figure 2. The Raman peak in the C₂H₆+NH₄Br hydrate was detected at 994 cm⁻¹, while those in sI simple C₂H₆ hydrate and solid C₂H₆ were at 1000 cm⁻¹ and 997 cm⁻¹, respectively. Raman spectra of N-H stretching vibration of NH₄⁺ in the C₂H₆+NH₄Br hydrate are shown in Figures 3b and 4b. Figure 4 corresponds to the enlargement of 3200 to 3350 cm⁻¹ in Figure 3. Figures 3 and 4 include the Raman spectra in the simple C₂H₆ hydrate (a), the solid NH₄Br powder (c), and the quenched NH₄Br aqueous solution (d). All samples were recorded at 77 K and 0.1 MPa. As shown in Figure 3, the intensive Raman peak was detected around 3040 cm⁻¹. In the solid NH₄Br powder (c) and the quenched NH₄Br aqueous solution (d), the peak was detected at 3036 cm⁻¹, which agrees with the N–H stretching vibration of NH₄⁺ in pure crystalline NH₄Br [26]. In the C₂H₆+NH₄Br hydrate (b), the peak was detected at 3041 cm⁻¹ that is 5 cm⁻¹ different from the spectra (c) and (d). This Raman peak suggests the restricted NH₄⁺ similar to that in the crystalline NH₄Br exists in the C₂H₆+NH₄Br hydrate, which implies that the C₂H₆+NH₄Br hydrate might be a semi-clathrate hydrate like TBAB semi-clathrate hydrate. The 2nd largest difference between the

spectra of (b) and others (a, c, and d) appears around 3275 cm⁻¹, as easily recognized in Figure 4. Only the spectrum in the $C_2H_6+NH_4Br$ hydrate has the peak detected at 3275 cm⁻¹. Price et al. [27] estimated that the N–H symmetric stretching vibration of free NH_4^+ should be detected at 3270±25 cm⁻¹. The peak of 3275 cm⁻¹ implies the existence of possible relatively-free NH_4^+ in the $C_2H_6+NH_4Br$ hydrate. There would be a possibility of an NH_4^+ enclathrated in a hydrate cage. Further investigation would be needed to clarify the location of NH_4^+ in the $C_2H_6+NH_4Br$ hydrate.

The three-phase equilibrium curves of hydrates formed in the ternary system of $C_2H_6+NH_3+$ water are listed in Table 2 and shown in Figure 5. At both molar ratios of 1/35 and 1/23, the equilibrium curves are shifted to low-temperature and high-pressure side and almost paralleled with that of the simple C_2H_6 hydrate. It means, under the present experimental temperature and pressure conditions, NH_3 plays a role as a thermodynamic inhibitor for the simple C_2H_6 hydrate formation, like for the simple CH_4 hydrate formation [15]. However, comparing its inhibition effect with that in $C_2H_6+NH_4Br+$ water under the same molar concentration, the inhibition effect of NH_3 is quite smaller than that of NH_4Br . One of the reasons why the difference occurs would be the different degrees of ionization between NH_4Br and NH_3 in their aqueous solutions. NH_4Br is completely ionized while the degree of ionization of NH_3 is 10^{-3} order even at 100 MPa [28].

4. Conclusions

The possible incorporation of NH₄Br into C_2H_6 hydrates has been investigated with the phase equilibrium measurement and Raman spectroscopy. Two trends of phase behavior were observed in the ternary system of $C_2H_6+NH_4Br+$ water. One implies the formation of a $C_2H_6+NH_4Br$ hydrate. Raman spectra derived from NH_4^+ in the formed hydrate also imply it is a $C_2H_6+NH_4Br$ semi-clathrate hydrate. The other trend of phase behavior indicates the thermodynamic inhibition effect of NH_4Br on the simple C_2H_6 hydrate formation. The structural transition point between the $C_2H_6+NH_4Br$ semi-clathrate hydrate and the C_2H_6 hydrate inhibited with

NH₄Br is located at 282.4 K and 2.31 MPa with the NH₄Br/H₂O molar ratio of 1/35. The inhibition effect of NH₄Br was much larger than that of NH₃ under the same mole fraction in the aqueous solution. Under the present experimental condition, no NH₃ molecule occupies the hydrate cages.

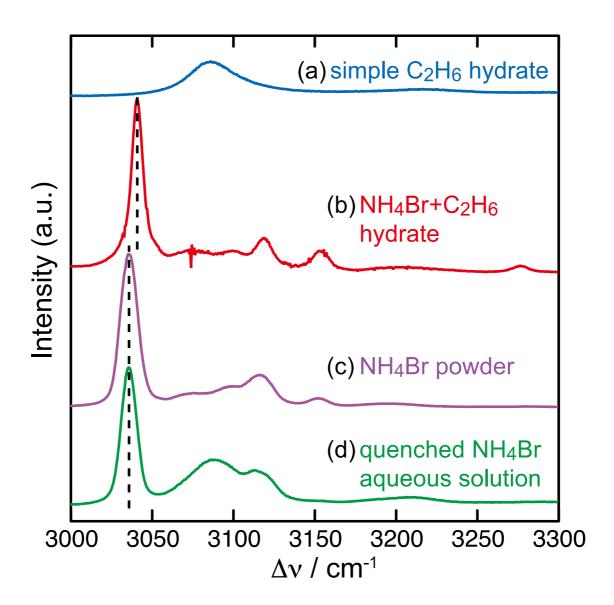

Fig. 3. Raman spectra of the N–H stretching vibration of NH_4^+ in $NH_4Br+C_2H_6$ hydrate (b), powder NH_4Br (c), and quenched NH_4Br aqueous solution (d). The spectrum (a) corresponds to the O–H vibration region in the simple C_2H_6 hydrate. All spectra were recorded at 77 K and 0.1 MPa.

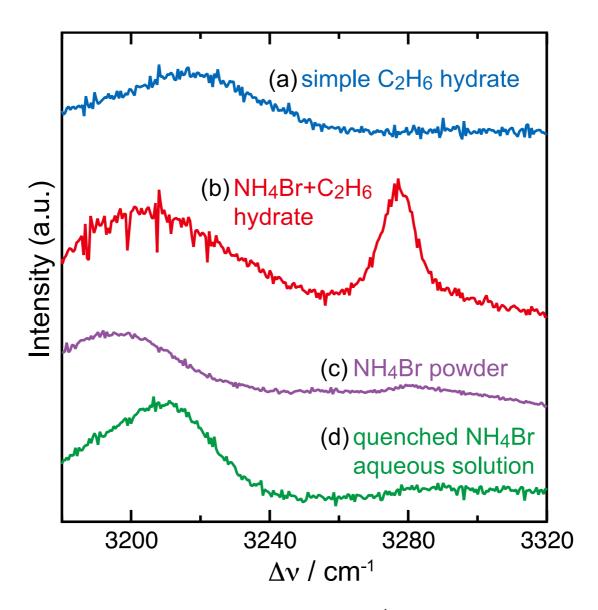

Fig. 4. Enlargement around 3280 cm⁻¹ in Figure 3.

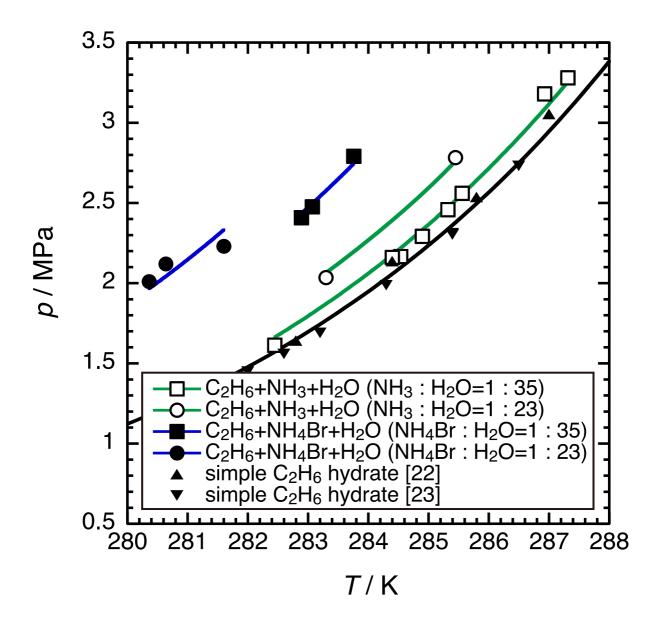

Fig. 5. Three-phase equilibrium curves of C_2H_6 hydrate+aqueous+gas phases in the ternary systems of C_2H_6 +NH₃+water (green curves) and C_2H_6 +NH₄Br+water (blue curves) and the binary system of C_2H_6 +water (black curve) [22,23].
